H.W

In Java every object has hashcode. Find out what is Hashcode, why it is being generated in Java.

A hashcode is an integer value generated for every object in Java by using the hashcode() method of the object class. It is used to identify an object and helps Java store and retrieve objects efficiently in collections like HashMap

HashSet, and Hashtable.

Objects that are equal should have the same hash code. However, two different objects can sometimes have the same hashcode, which is called a hash collision.

Example:

```
String s = "Hello";
System.out.println (s.hashCode());
```

Keypoints:

Every Java object has a hashcode() method.

It returns an integer value.

It is mainly used in hash-based collections for faster searching and retrieval. Equal objects must have the same hash code.
